SUMMARY

Liquid water presents one of the greatest challenges to those specialized in the Physics of Liquids. Its many unusual properties have not yet been rationalized in terms of a rigorous structural model, although considerable effort has been devoted to the subject. A quantitative treatment is not within our reach at the present time, but a reasonable qualitative understanding of the physical processes occurring in water has been obtained.

BNS empirical potential for water.

CEVERALITIES

The fact that our present knowledge of the liquid state compares unfavorably with our understanding of the solid or gaseous phases should not be surprising. The necessary approximations permissible for the latter two phases are simply not adequate for the description of the interactions between the molecules in the liquid state which are not localized on a regular lattice as in a solid, or are not so far apart that their interactions can be neglected as in vapors. Much progress has been actions can be neglected as in vapors. Much progress has been achieved, however, in the case of simple liquids (Argon) and of "nodel" liquids (fard-Spheres, Lennard-Jones) thanks to the use of large scale computers. On the other hand, a rather limited amount of detailed information is available for liquids with more intricate potentials of interaction such as water.

That one should have a scientific interest in water could perhaps be justified only by the fact that life as we know it, would not exist without it. Its importance as a life sustaining medium for all living organisms and as a building block for organic macro-molecules has been well established. Industrial applications, such as the processes of polymerization, depend very much on the knowledge of the properties of water.

Our present incomplete understanding results not only from an insufficient amount of reliable data and the inadequacy of present theoretical methods, but also from the difficulties encountered in the synthesis of a picture of the structure of water from very diverse sources of information. Data resulting

from X-ray and neutron scattering, infrared and Raman spectroscopy, acoustic and dielectric relaxation studies, quantum mechanical and classical statistical mechanical calculations as well as computer simulation, must first be rigorously analyzed and then interpreted in terms of common concepts. One cannot hope for expertise with all these different methods, but it is possible to build a tentative picture of what water appears to be like on the basis of present generally accepted results. Such is the motivation for the first part of this thesis, which deals with past and more recent work by various searchers studying the problem of the structure of water.

THE PROPERTIES OF LIQUID WATER

I- Thermodynamic properties

A Specific volume and thermal expansion.

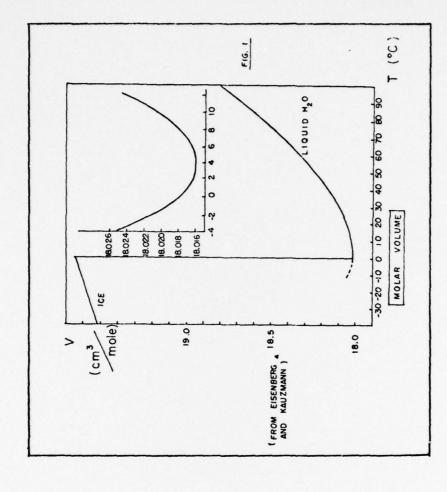

That the solid phase of water is lighter than its liquid phase is a rare enough phenomenon, even though some solids with open modes of packing share this property, as in the case of Germanium. The really outstanding fact is that water has a minimum in molar volume (a maximum in density) at 3.98 C above its melting point under one atmosphere. Under higher pressure the temperature of maximum density has been found by Kell to vary linearly and negatively:

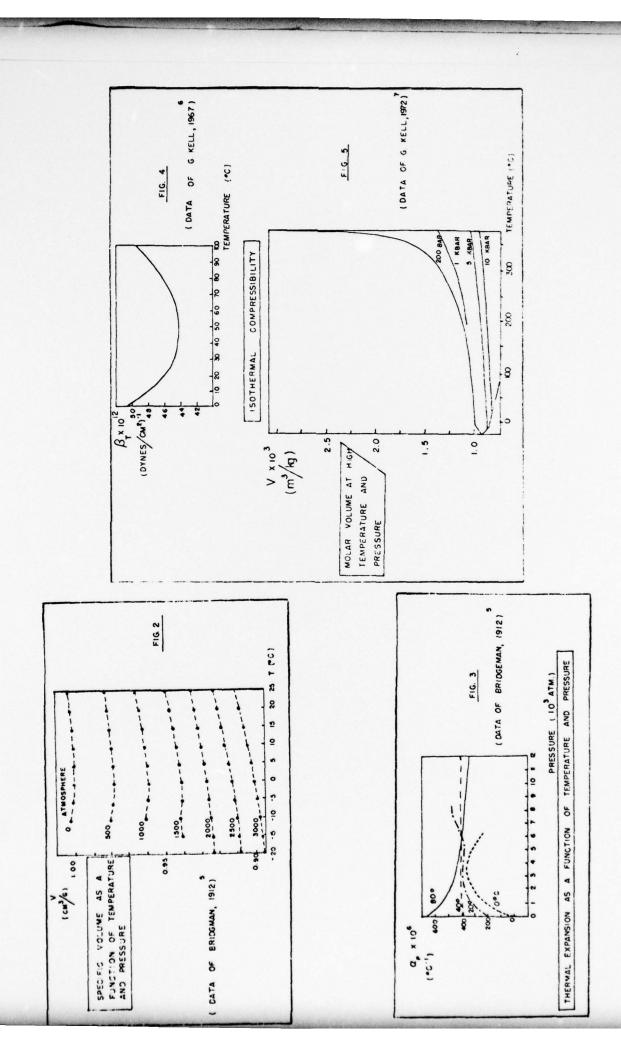

$$\left(\frac{8T}{8P}\right)_{\text{pass}} = -0.020 \pm 0.0003$$
 °C BAR

atmospheric and under elevated pressure, is depicted in figures 1 and 2 respectively. Figure 3 shows the dependence of the coefficient of thermal expansion on pressure at several temperatures. Up to 40 C, $4 \text{ C} = (8 \text{ V}/87)_p/v$ also behaves anomalously as the pressure is increased. For most liquids, there is a monotonic decrease of 4 with increasing pressure, as shown in the 80 C curve in figure 3.

B Isothermal compressibility.

For most liquids, the coefficient of isothermal compressibility increases monotonically with increasing temperature. In liquid water, $\beta_{\rm T}=-(~8\,\nu\left/8\,\rm P)_{\rm T}/\nu$

displays a minimum value at 46 C under atmospheric pressure. This is shown in figure 4, which is a plot of β_T as a function of temperature under one atmosphere.

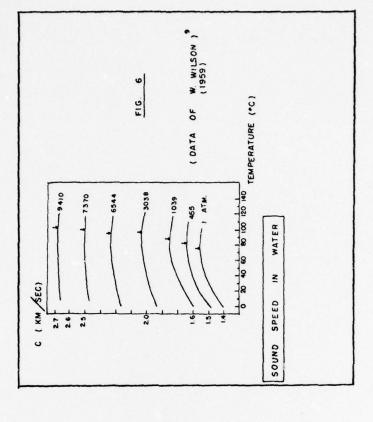

As the pressure is raised, the minimum of β_{\uparrow} is displaced to a higher temperature and the minimum becomes less marked.

Figure 5 depicts the high pressure, high temperature behavior of the molar volume of water. The stable liquid range is shown up to the critical point. An observation can be made readily: the molar volume of liquid water behaves similarly to most liquids in the region of high temperatures and pressures. The ancmalous phenomena seem to occur only in the region of molarate temperature and pressure.

Sound velocity

Together with the unusual behavior displayed by the density and compressibility, the sound velocity is also anomalous in liquid water. Figure 6 displays the temperature dependence of sound velocity in distilled water under one atmosphere. The maximum value at 74.5 C is the salient feature considering the fact that in most other liquids the sound speed decreases monotonically as the temperature is raised.

Smith and Lawson (1954) have measured the sound speed as a function of pressure at different temperatures. Some of the results are reproduced in figure 6. One effect of pressure, it is revealed, is to drive the temperature of the maximum value up, and to decrease its sharpness.

-8-

- 10-

D - Thermal properties.

The heat capacity of liquid water is large . At constant pressure it has the value of about 18 cal/mole C at 0 C. The temperature variations of the heat capacities at constant pressure and at constant volume are displayed in figure ?.

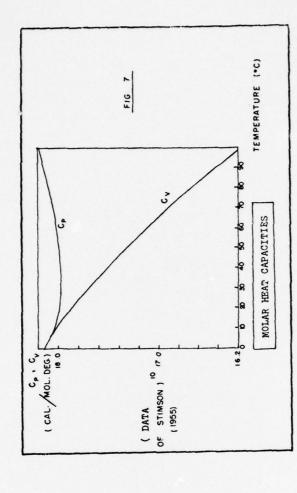

Cp shows a slight minimum at 35 C and Cv is decreasing monotonically. Table I is reproduced from Eisenberg and Kauzmann's book and lists the various changes in internal energy, entropy, and heat capacity upon phase transition. The relatively large increase in heat capacity observed upon fusion is generally attributed to the structural changes possible in the liquid phase. The additional energy involved would be used to either distort or break hydrogen bonds in the liquid.

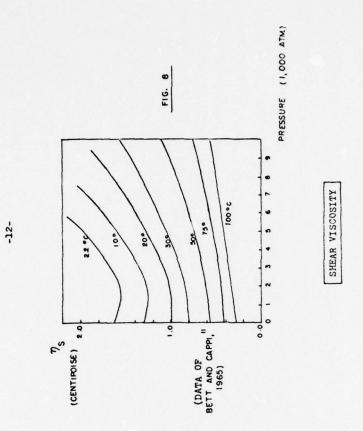

II- Transport properties.

A - Viscosity

Liquids generally become more viscous when pressure is applied to them. Mater is an exception to this rule as figure g illustrates. As the pressure increases, the value of the shear viscosity η_s decreases and reaches a minimum for temperatures below 30 C. Davis and Jarzynski have measured the volume viscosity

 η_{ν} and have found its behavior to be qualitatively similar to the one of η_{s} . Moreover,the ratio η_{ν}/η_{s} was found to remain constant within 20 % at all temperatures between 0 C and 90 C, and at pressures up to 1,650 bars.

B - Heat conductivity

130 C (under saturation conditions'), and decreases monotonically up to about 150 C. Most liquids have a continously decreasing heat conducus parabolic temperature dependence. It has a maximum value at about The thermal conductivity of water has an approximately tivity as a function of temperature : The behavior of thermal conductivity in water is then also anomalous

III - Molecular properties.

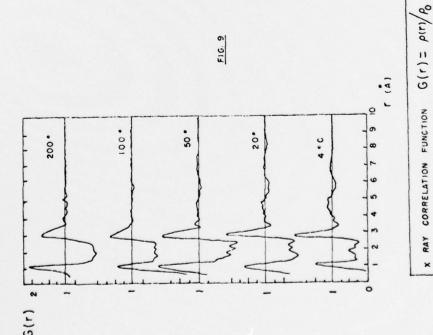

A - The radial distribution function

can be obtained through X-ray or neutron scattering experiments. The intensity of the scattered beam is measured as a function of the scattering angle. Structural information is obtained through Information about the average local structure of water numbers of atoms of type j situated at a distance R from atom i. a modified Fourier transform of the intensity which eventually generates the various functions $\rho_{\rm i}$ (R) giving the average In the case of water there are three such functions :

tions of the different types of pairs of atoms from the scattering and hydrogen atoms. Narten and Levy have estimated the contribuof X- rays and neutrons. They found that most of the scattering the 0-H pairs and H-H pairs were only 12% and 2% respectively was being done by the 0-0 pairs while the contributions from for the various oxygen POO(8) . PHH (8) . POH (8) of the 0-0 pairs contribution.

tions (0-0, 0-H, H-H) must be performed for a rigorous measurement have been performed. Thus, derivation of the radial distribution neutron diffraction experiments are only probes for the average scattering in water and neutron scattering in heavy water (\mathcal{D}_20) of models for the local structure of water. One such model used the results of a single X- ray or neutron scattering experiment at this point in order to be able to judge the merits of scat-(over a volume large with respect to the molecular dimensions) involving an emphasis on the three different types of interac-Two important qualifications have to be introduced tering results and their impact on the problem of the strucof the individual $\rho_{i,j}(R)$. In practice only reliable X-ray of the actual instantaneous structural configurations. It is by Narten and Levy employs a single parameter, the remaining inter-atomic dimensions being constrained by the tetrahedral ture of water : First, one must keep in mind that X- ray and functions from the experimental results has required the use not possible to infer the instantaneous structure. Secondly, substance. In the case of water, three separate experiments requirement and by known values for interatomic parameters. cannot yield the different $\rho_{i,j}$ (R) for a heteroatomic

The results of Narten and Levy are plotted in figure 9. The results are for X- ray diffraction in liquid water at equilimeasure of the local deviation from long range random behavior. $G(R) = \rho(R)/\rho_o$ (where ρ_o is the bulk average dengity of molecules) is the radial distribution function and gives a brium with its vapor.

(Data of Narten and Levy, 1972)

-16-

The first peak at 1 A is attributed to the Oxygen-Hydrogen first neighbor interactions. The maximum at 2.9 A reflects the Oxygen-Oxygen, nearest neighbor effect. The two broad peaks at around 4.5 A and 7 A depict second and higher neighbor interactions. The small structures between 3.5 A and 4.0 A are not assigned any structural meaning.

B - The evidence from Infrared and Raman spectroscopy

1 - The Infrared spectrum of liquid water

Infrared and Raman spectroscopy are very sensitive detectors of the effects of molecular interactions. They reveal the fundamental frequencies of molecular vibrations thus proting the molecular structure and intermolecular forces. Spectroscopic studies of liquid water are fundamental to the question of solving the problem of the possible classification of different molecular species in terms of their environment.

The normal vibrational modes of isolated water vapor molecules, and of bonded molecules in liquid water and ice are listed in Table II. ν_1 , ν_2 , ν_3 are fundamental intranolecular vibrational frequencies of the isolated vapor molecule. For 0-H stretching in pure $\rm H_2O$ vapor they are $3651~\rm cm^{-1}$, $1595~\rm cm^{-1}$, and $3755~\rm cm^{-1}$ respectively. In the condensed phases the molecules are bonded to one another and additional intermolecular vibrations are introduced. These modes are also described in Table II.

An important consequence of the hydrogen bonds between molecules, however, is their effect upon the frequencies of intramolecular vibrations. In particular, hydrogen bonding tends to shift the infrared and Raman spectral components characteristic of

O-H stretching modes to lower frequencies and the H-O-H bending mode to higher frequencies. For a detailed treatment of the spectroscopic study of the hydrogen bond, one can refer to the book by Pimental and Mc Clellan. Thus, in liquid water the frequencies of both stretching modes are estimated to be around 3420 cm⁻¹. This is lower than the corresponding frequency in the vapor state but larger than the one in ice. This reflects the relative strength of the hydrogen bond in the two condensed phases: The molecules in ice are more strongly bonded to one another.

A typical infrared spectrum obtained from a thin layer of liquid water is reproduced in figure 10. The various absorption bands correspond to the various intramolecular modes (at 3400 cm⁻¹, 1650 cm⁻¹) and intermolecular modes (at 680 cm⁻¹, 200 cm⁻¹). Some combination modes are present (2120 cm⁻¹, 4000 cm⁻¹); they result from the association of intra and intermolecular vibrations.

The variation with temperature of the degree of hydrogen bonding can be obtained through the observation of shifts in vibrational frequencies with temperature charge. Such a study is shown in figure 11. Raising the temperature seems to drive the frequencies to higher values; a trend towards the free molecule state. Either weakening or breaking of hydrogen bonds could provide an explanation of such a phenomenon. More quantitative studies can be made in the infrared overtone range; one may refer to the article by M.A. Luck for more details on the estimates of the degree of hydrogen bonding under various conditions.

-20-

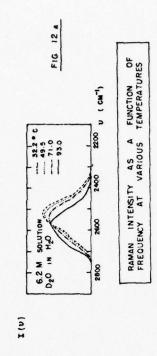

Because of its ability to probe the instantaneous environment distances in the liquid state. This would result in an increased versus continuum controversy. In particular the interpretation invoked to prove or disprove opposite viewpoints in the mixture of infrared and Raman spectra has been the center of debates arrangements. Indeed, if the instantaneous configurations of and finite way, the spectmal distribution of the light intenvariation in potential which would affect the intramolecular relating to the possibility of differentiating the molecular band for such a mode is singly peaked argues for a continuum the molecules of the liquid can be classified in a discrete sity would reflect such discreteness. In addition, the 0-H wider than that in ice. This widening of the band has been vibrational band of the O-H stretching mode has been particularly well studied. The fact that the infrared spectral model. Such a continuous distribution in frequency of the mixture models which advocates a small number of molecular (uncoupled) stretching band in the liquid is considerably light intensity exiting from a water sample contradicts taken to reflect the greater variation in intermolecular of the water molecule, vibrational spectroscopy has been environments from the shape of the spectral bands. The vibrational frequency.

Proponents of the mixture model have attempted to explain the shape of the spectral band by decomposing it into a small number of Gaussian distributions, each of these being characteristi of a particular molecular configuration. Unfortunately, such decomposition cannot be achieved in a unique fashion.

the dielectric constant, the main relaxation time, and the spread tation of the molecular motion and cannot be taken as the individenoted by α . It must be noted that τ_0 is a macroscopic manifes-Table III presents some results of microwave measurements giving reorientation given by dielectric relaxation can be described by a single relaxation time T_D . Liquid water is essentially such a case. However, there is strong evidence for the existence of dual molecule rotation time, which should be somewhat shorter. For some liquids the macroscopic rate of molecular a small spread in relaxation time which could be caused by a number of different relaxation times very close together.

The theory of rate processes gives the temperature dependence for cases with a single relaxation time as

$$2\pi/\tau_D = \omega_S = C \exp(\Delta s_0/R) \exp(\Delta \epsilon_0/RT)$$

approximate determination of ΔE^* gives a value of about 5 kcal/mole with its small spread in terms of hydrogen bond bending or breaking have been considered by Elsenberg and Kauzmann (p.209 in their book). in the case of liquid water. This value is close to what is genethe breaking of a single hydrogen bond. The different interpreorientation process for dipole relaxation is likely to involve where ΔS^* and ΔE^* are the entropy change and the activation energy of the relaxation process. From experimental values, an tations of the existence of a single relaxation time together rally accepted as the energy of hydrogen bonding. Thus, the

This concludes our brief survey of the currently available experimental evidence on liquid water in its stable state. The second of th

Due to the diversity of the sources of information on the subject, to the problem of structure while pointing to current areas of characteristic properties of liquid water and their relations this present treatment has been very incomplete; it is hoped, however, that even such a short presentation may reveal the debate. For more comprehensive treatises one is invited to refer to the compilations by Franks, Horne, and Luck.

We now turn our attention to the properties of metastable liquid water. -28-

1

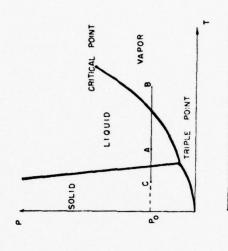

THE PROPERTIES OF METASTABLE LIQUID WATER

I - The thermodynamic description and some basic facts from nucleation theory.

the conditions of temperature and pressure at which phase transorwhen the new phase must appear in the bulk of the original phase, The liquid can then remain in a state of metastable equilibrium phase to be nucleated. The surface free energy of the new phase The usual range of the liquid state is determined by phases involved are in contact with each other. In the cases where its bulk chemical potential is higher than that of the mations occur (vaporization or solidification) when the two the onset of the transition is often considerably delayed. acts in this case as an energy barrier to nucleation.

three possible states of the substance. Point A represents a stable state of liquid water. A superheated state can be reached (point B) pressure isothermally to reach point B. Similarly, a liquid sample if the temperature is raised isobarically and the sample remains can be supercooled by reducing the temperature under constant diagram of water. The three coexistence lines separate the Figure 15 is a schematic representation of the P-T in the liquid state. This can also be done by reducing the pressure to reach the point C.

the growth to macroscopic size of "critical" embryos (or fuclei") In the kinetic approach to the problem of homogeneous nucleation the phase transformation is viewed as resulting from of the new phase in the midst of the original phase. The second secon

WATER

9

DIAGRAM

PHASE

P. T

As a result of density fluctuations, small embryos of the new phase are formed. Because of the constant attachment and detachment of molecules, these embryos are not in equilibrium, except when they reach the "critical" size at which point they are in a state of unstable equilibrium and may readily grow to macroscopic size. The equilibrium distributions of the vapor embryos and the work required for their creation have been determined for a superheated liquid. This work is maximum for the formation of a "critical" embryo and can be written

$$W_{C} = 16 \pi \sigma^{3} / (P - P_{L})^{2}$$
,

where σ is the surface tension, P is the pressure in the vapor savity, and P_L is the pressure in the liquid. The magnitude of \aleph_c varies with the degree of superheating or supercooling. In the case of a supercooled liquid, the expression for \aleph_c is further complicated by the anisotropy of σ and by the nature of the solid surfaces of the embryos.

The "classical" theory of nucleation as formulated by Volmer ²⁶, Becker and Doering²⁷, and Prenkel²⁸, among others, provides a way to determine approximately the rate of formation of critical embryos in the steady state regime. Under steady state conditions the net rates at which the different size embryos grow are all equal and their distributions are stationary. The rate of creation of the critical embryos is related to the work of formation through the relation

In the case of supercooled liquids an additional effect is introduced by the viscous forces which tend to impede the rearrangements of the molecules. In general, the description of the rate of critical nuclei formation in supercooled liquids involves an activation energy $\mathbf{E}_{\mathbf{A}}$ for molecules crossing the solid-liquid interface. The relation becomes then

-30-

$$J = C'(T) \cdot \exp(-E_A/kT) \cdot \exp(-W_O/kT)$$

In the constant C'are included factors relating to the attachment and detachment coefficients for the molecules which are often approximated when actual calculations are performed. The coefficient C' is temperature dependent.

Numerous modifications and emendations to the "classical" nucleation theory have been introduced. Their aims have been to correct certain computation errors and oversimplifications which were originally introduced. The basic relation between the work of critical nuclei formation to the rate J is, however, still the common approach adopted. For a more detailed discussion, one may refer to Dunning's review article in the monograph on Nucleation edited by A.C. Zettlemoyer.

II The experimental data on supercooled and superheated water.

Experimental measurements in metastable liquids are difficult to perform because of the stringent requirements of purity and isolation of the samples. It is then not surprising that the amount of available experimental data for thermodynamic parameters of liquids in their supercooled or superheated

states is quite small. In the case of liquid water, however, a growing interest in the supercooled range has produced a respectable bank of thermodynamic data. The superheated state of water, on the other hand, has not been studied extensively. Some experimental parameters relating to the predictions of nucleation theory (tensile strength³⁰, limit of superheat²) have been determined, but virtually no thermodynamic quantities, except for the density, has been measured.

1 - Supercooled water.

a) Density.

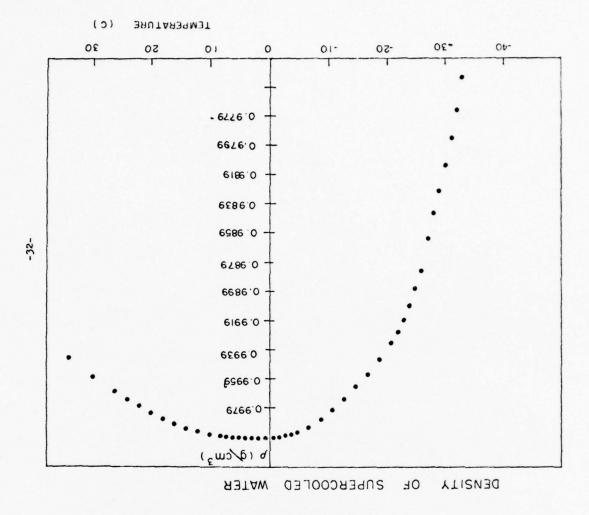

The density has been measured under atmospheric pressure by Zheleznyi 34 down to -34 C and Shuffle and Venugopalan 34 down to -38 C. Figure 16 reproduces Zheleznyi's data as a function of the temperature. An outstanding feature is the accelerating decrease of the density with decreasing temperatures. The coefficient of thermal expansion $\alpha = (8 \text{V} \setminus 8 \text{T}) / \text{V}$ is negative and decreases extremely rapidly.

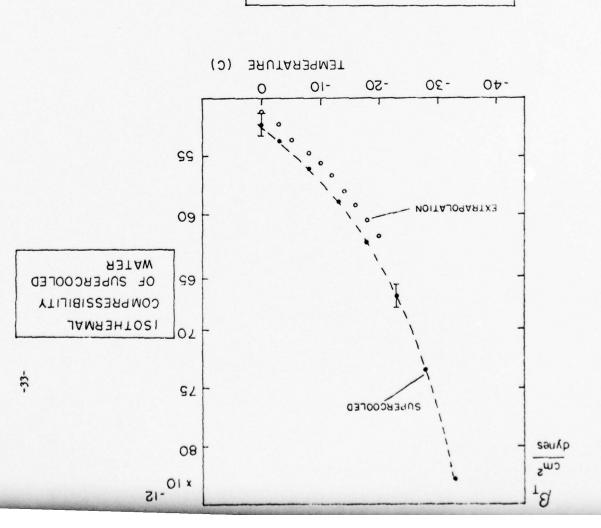

b) Isothermal compressibility.

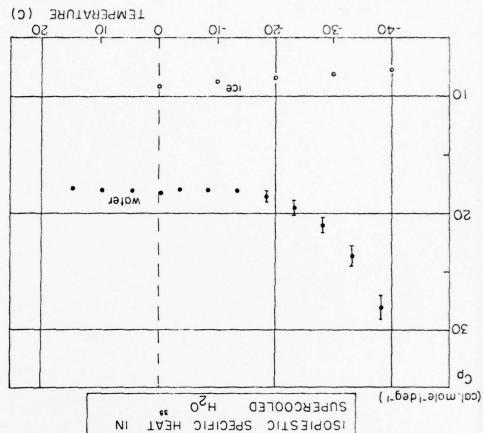

The coefficient of isothermal compressibilty β_T has been measured by Speedy and Angell 33 down to -26 C. Their results are reproduced in Figure 17 and reveal a slightly higher value for β_T at low temperatures than that determined from an extrapolation of data above 0 C.

Specific heat.

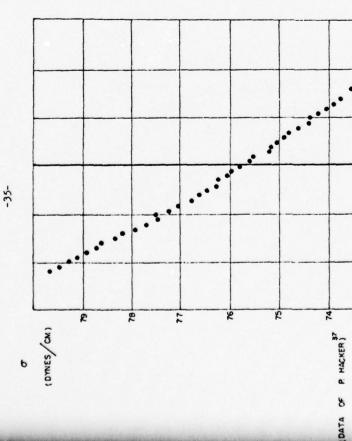

Rasmussen and MacKenzle and Angell et al. have measured the specific heat at constant pressure \mathbb{C}_p (isoplestic heat capacity) in water supercooled to -38 $\mathbb C$ by means of emulsions.

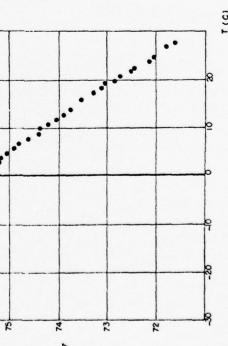

-34-

SURFACE TENSION

FIG 19

The results of Angell et al. are reproduced in figure 18. An anomalous increase in C $_p$ below -15 C can be observed. The calculation of the specific heat under constant volume (C $_v$) reveals that it remains relatively constant down to -38 C.

This phenomenon has been given two different interpretations: The first involves a thermodynamic singularity at -45 C, and the second invokes the concept of precrystallization. A discussion of an interpretation for the temperature dependence of $_{\rm p}^{\rm p}$ will be offered in the last chapter of the companion report.

d) Viscosity.

Hallett has measured the viscosity of water down to -24 C. The results show a smooth continuation of the data in the stable range, although the rate of increase of the viscosity with falling temperature is larger than that determined simply from an extrapolation of the data above 0 C.

e) Surface tension.

P.Hacker has been able to determine the surface tension down to -24 C. A slight but abrupt change in the temperature coefficient may be detected at about -5 C (see Fig. 19).

f) The self-diffusion coefficient and proton relaxation time.

The self-diffusion coefficient has been determined by

H. Pruppacher down to -20 C and by Gillen et al. down to -31 C.

An interpretation of this data has been offered recently by

Ao

Ricci et al. who have generalized the Macedo-Litovitz theory
of diffusion by incorporating the influence of the average number
of broken hydrogen bonds.

The temperature and pressure dependence of the longitudinal proton relaxation time ($\mathbf{T}_{\mathbf{l}}$) have been recently studied by lang and

Lüdemann . An anomalous increase in T₁ with an initial increase in pressure under isothermal conditions has been detected in the temperature range between +20 and -66 C. The experimental data have been fitted with an empirical two-exponential relation developed by Hindman. The anomalous pressure dependence of T₁ has been attributed to pressure effects on the random hydrogen bonded network present in liquid water at these low temperatures.

2- Superheated Water.

Chukanov and Skripov and Kell and Whalley have measured the density of superheated water under moderate and high pressures. Data at atmospheric pressure have been obtained through an extrapolation. According to their results, the temperature and pressure behavior of the density in superheated water is qualitatively similar to that of the stable liquid above room temperature.

The sound velocity has been measured in liquid water above 100 C tut under saturation conditions. Although the liquid is not superheated in these circumstances, it is expected that the temperature dependence of the sound velocity thus measured is not very different from that found in the superheated liquid, at least at temperatures not very much higher than 100 C.

What has been listed above is essentially the currently available experimental information on metastable liquid water. In the next chapter we will consider the theoretical treatment of the problem of the structure of water.

CHAPTER II THE STRUCTURE OF LIQUID NATER: THEORY

INTRODUCTION

of the energy of hydrogen bonding, betrays the modest progress which water can be classified in a discrete or continuous manner in terms much success as the 'mixture' models in accounting for the various the various ad-hoc structural models involving the idea of a mixalso proposed within the 'continuum'framework and generally met as instantaneous environment of a water molecule is seen as varying fundamental question as to whether the molecular aggregations in has been achieved since Roentgen first proposed his speculations of such a theory, and they remain today the conceptual basis of components. The unusual thermodynamic properties, specifically the PVT properties, were the principal reasons for the proposal ture of discrete components. Empirical structural models were state of affairs in this field. Indeed, the debate about such thermodynamic anomalies found in water. In this approach the about the existence of a mixture of "icelike" and "un-icelike" The nature of one of the main controversies in the theory of the structure of liquid water reveals the general not in a discrete way but in a continuous manner

An alternate way of undertaking the theoretical study of the structure of water is to start from the basic principles of statistical thermodynamics and to derive a partition function for the system under study. The rigorous solution of the appropriate equations, however, remains a quite insurmountable task

ween the many water molecules. The adoption of the assumption of pairwise additivity for the interaction potential has led to some progress in both of the available methods for research. The first method, based on the solution of the integral equations involving the pair distribution function, has provided some useful insights into the structural properties of liquid water. The alternate path comprises either the Monte Carlo or the Molecular Dynamics approaches and has revealed itself to be more fruitful.

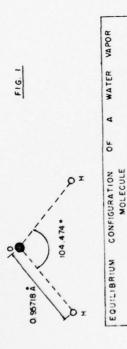

In this part of the thesis a review of works on water structure is attempted. Evidence from both theoretical and experimental sources employing various methods is examined. A tentative picture of the present status of the field is thus proposed.

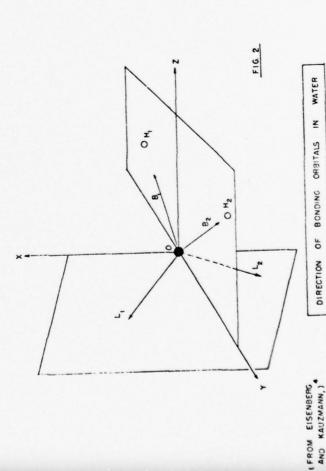

We proceed by first considering the properties of the water molecule and of the all important hydrogen bond.

THE WATER MOLECULE

The apparent simplicity of an isolated water molecule conceals the wealth of intricate interactions and anomalous phenomena found in the molecular aggregations of the liquid state.

The equilibrium configuration of an isolated water vapor molecule is depicted in Figure 1. The molecular properties of water can be obtained by both theoretical and experimental means. Within the framework of the Born-Oppenheimer and

-43-

water, which seems now to be an undisputed fact, is a direct consequence of this charge distribution.

THE HYDROGEN BOND

The lone pair hybrids can effect a hydrogen bond with the protons of any two other water molecules. Figure 3 illustrates the resulting tetrahedral coordination found in iceI. The hydrogen bond is the result of a mostly electrostatic interaction between the molecules. However, other effects, such as delocalization (or distortion of electron clouds), repulsion due to the overlap of electron clouds, and dispersion forces due to the induced polarization caused by the instantaneous charge distribution, are also present. For more details one may consult the works by Coulson⁵⁰. Theoretical quantum mechanical studies of the hydrogen bond have been performed, and detailed reviews of these works can be found in the articles by C.N.R. Rao and P. Shuster³⁸.

The important geometrical parameters here are the numbers of hydrogen bonded molecules around a given single molecule, and the value of the 0-0 angle between two bonded molecules. These parameters are of crucial importance in the discussion of the properties of the 'mixture' and'continuum' models.

quantum mechanical studies of water dimers, trimers, and polymers have indicated that the energy of hydrogen bonding for a water molecule depends upon the number of hydrogen bonds in which this particular molecule is already engaged. Specifically, the energy of the H-bond in a trimer is greater than that in a

dimer. This tends to imply that hydrogen bonding in water is a cooperative phenomenon involving more than two molecules. This cooperative property is a consequence of the non-additivity of the potential energy of interaction among the molecules forming the liquid.

An additional remark should be made concerning the energy of hydrogen bonding. There is no agreed definition of this quantity, and this concept has been applied in different ways in the computations by different authors. Eisenberg and Kauzmann have listed a few possible definitions. In evaluating the predictions of specific works, care should be used to choose the appropriate definition.

II THE EMPIRICAL MODELS FOR THE STRUCTURE OF WATER

The great majority of the earlier models were based on empirical evidence. The typical procedure was a physically intuitive postulation of the existence of certain types of molecular environments. Calculations of the properties of the resulting fictitious substance were carried out through statistical mechanical methods complemented by various assumptions. A varying number of undetermined parameters could be adjusted to obtain the best fit to experimental data. Although very reasonable agreements have been obtained in many cases, this procedure has been amply criticized because of the failure to provide satisfactory accounts for many properties other than the ones the various models had been specifically designed to simulate. In addition, because this approach does not have any firm theoretical foundation, it allows too great a freedom in interpreting the existing

-45-

physical evidence. In other words, it has been found that too many intuitively postulated molecular structures can be made to agree with experimental observations. Consequently, in some cases this has led to drastic oversimplifications which may have been a significant contributing factor to the origin of the heated controversy about the respective claims of the 'mixture' and'continuum' models.

Striving for a more rigorous approach, some workers have attempted to adapt the cell and lattice theories to the problem of water structure. While this path provides a more theoretically satisfying point of view, it has not yet been shown that this approach can be physical enough to be useful. The main drawback is the postulation of a regular lattice in order to describe a fluid.

Computer simulation as applied to the study of water structure eliminates the need for the postulation of any a priori structure and, in theory, should allow for a more rigorous statistical mechanical treatment. In practice, other kinds of approximations must be made and their consequences have not yet been fully appraised.

In this section the empirical or ad-hoc models are treated first and the different aspects of the 'mixture' and 'continuum' models are discussed. The cell and lattice models are examined next, and finally the integral equations and the computer simulation methods are treated.

Many reviews of the works on water structure have appeared in the literature ; consequently, most of the achievements and

F1G 66

of the molecules. In order to simplify the analysis, Pople has assumed that the energy of the H-bond is symmetrical in the azimuthal direction and is additive with respect to the angles φ and φ' . The possibility of bond stretching is also neglected, leading to the constant 0-0 distance denoted by $R_{_{\rm O}}$. Consequently, the azimuthal variations average out and the expression for the bond energy can be written as

$$E = F(\phi') + F(\phi) .$$

An explicit form of the function F(A) is taken as

$$F(\phi) = F_0 - g\cos\phi$$
.

The constant g is called the hydrogen bond bending constant and it is given by

$$B = (d^2 F/d\beta^2)_{\phi=0}$$
.

Using classical statistics as a first approximation, Pople has calculated the average bond-bending angle. This was found to be equal to 26 and 30 degrees at 0 and 100 C respectively.

1 The Radial Distribution Function.

The PDF has been calculated using the formalism of this agreement is obtained with the data of Morgan and Warren for the distribution of the oxygen atoms. An important feature of the model is that it allows the collapsing(towards the central molecule) of molecules belonging to the second and third coordination shells. This is consistent with the value of 4.4 for the coordination number of the first shell, and with the higher density in the 3.5 A region when compared with the density of ice.

-69-

The Variations of the Density upon Fusion.

A semi-quantitative treatment has provided an explanation for the density increase at the melting point of ice. This anomalous phenomenon is attributed to the collapse of the structure in the second and third coordination shells. An estimate for the density increase due to the displacement of molecules in the second and third shell toward the center molecule was found to be 0.29 g/cm³. This compares favorably with the figure of 0.22 g/cm³ obtained by substracting from the true density of water at 0 C (0.9999 g/cm³) the density that would be found had the liquid retained an ice structure (0.78 g/cm³). The average hydrogen bond length was taken to be 2.90 A from the data of Moregan and Warren.

The Static Dielectric Constant,

The temperature dependence of the dielectric constant has been successfully predicted by this model in the region between 0 and 83 C. The absolute magnitude, however, has been found to be too low by about 20 %. This was believed to have been caused by the neglect of contributions to the electrostatic field by molecules beyond the nearest four neighbors. An improved agreement is obtained when molecules beyond the nearest four are considered.

Thermal Energy.

Eisenberg and Kauzmann have shown that the distorted hydrogen bond model of Pople could also provide an explanation for the value of the thermal energy of liquid water. They have determined the vibrational and configurational contributions to

-63

A relation between the shift of the frequency of the maximum of the uncoupled 0-H stretching band and the energy of hydrogen bonding was adopted. More distorted bonds were taken as causing higher frequencies. The configurational energy calculated with the help of this relation was found to correspond very closely to the experimental values. Hence, a continuum model has been shown to be consistent with the known experimental thermal properties of liquid water.

Another model based on distorted hydrogen bonds has been proposed by Bernal. In this case, the four coordinated molecules were given hydrogen bonds which could be considerably distorted. The molecules were supposed to be linked in an irregular network of rings. Bernal has reported a general agreement between calculations based on such a random network model and measured radial distribution functions.

This concludes the treatment of the empirical models for liquid water. Lattice and cell models are considered

molecules which are nearestneighbors is considered. In this case, the distinct values depending upon the mutual orientation of the neighmagnitude of this pair interaction potential is only allowed three additional assumptions are made. Only pair interaction between In order to evaluate the partition function, several boring molecules. The interaction potential is then given by

- $_{lpha lpha}$, = -E if lpha and lpha' correspond to orientations leading to hydrogen bonding,
- if rotation of one of the molecules is sufficient to allow hydrogen bonding,

BODY CENTERED CUBIC LATTICE USED BY FLEMING AND GIBBS

-69-

-e₂ if rotation of both molecules is needed to allow hydrogen bonding.

The numerical values of $E_{\rm B}$, ${\rm e_1},{\rm e_2}$ are kept adjustable in order to coincide with numerical values determined experimentally.

The Grand Partition function is written $\boldsymbol{B} = \boldsymbol{\Sigma}' \exp \left[\boldsymbol{\beta}_R \boldsymbol{R}_1^{\boldsymbol{\Sigma}} \boldsymbol{\alpha}_1 \left[\boldsymbol{U}^{1} \boldsymbol{n}^{\boldsymbol{L}} \boldsymbol{-}_{\boldsymbol{\mu}} \boldsymbol{-}_{\boldsymbol{\beta}}^{\boldsymbol{L}} \, \boldsymbol{1} \boldsymbol{n} (^{\boldsymbol{\nu}} \boldsymbol{c}/\Lambda^3) \right] \, \boldsymbol{n}_{\boldsymbol{\alpha}_1} \, (\underline{R}_1) \right]$ $\exp \left[- \boldsymbol{\beta}_{\boldsymbol{\beta}} \, \boldsymbol{\beta}_1^{\boldsymbol{\nu}} , \boldsymbol{\alpha}_2^{\boldsymbol{\nu}} \boldsymbol{\alpha}_1 \boldsymbol{\alpha}_2^{\boldsymbol{\nu}} (\underline{R}_1 \boldsymbol{-}_{\boldsymbol{R}_2}) \boldsymbol{n}_{\boldsymbol{\alpha}_1} (\underline{R}_1) \boldsymbol{n}_{\boldsymbol{\alpha}_2} (\underline{R}_2) \right] ,$

where u^{\inf} is an internal kinetic energy (vibrational or rotational motions), $n_{\alpha}(\underline{R})$ is the number of molecules at the lattice site situated at \underline{R} and with orientation α (one must have n_{α} =0 or 1, and \underline{R} $n_{\alpha} \leq 1$), μ is the chemical potential, $v_{\alpha_1\alpha_2}(\underline{R}_1-\overline{R}_2)$ is the pair interaction energy, $\Lambda = \frac{\beta h^2}{(2\,m^2)^2} p_{\mu}$ is the thermal wavelength arising from the contribution of the translational kinetic energy. The symbol Σ denotes the sum over all the allowed states of the system.

Calculations of the thermodynamic parameters are made to two orders of approximation. The first order is the Mean Field Approximation (MFA) which simplifies considerably the problem by replacing the potential acting on a molecule by the average potential due to the presence of its neighbors. In this case

 $\frac{R_1 \cdot R_2}{\alpha_1 \cdot \alpha_2} \alpha_1 \alpha_2 \frac{(R_1 - R_2)}{\alpha_1 \cdot R_2} \frac{\sum_{\alpha', R'} v_{\alpha \alpha'} \cdot (R - R') \langle \gamma_{\alpha'}, (R') \rangle}{\alpha_1 \cdot \alpha_2} = \frac{1}{12} \alpha', \frac{N}{R} \cdot v_{\alpha \alpha'} \cdot (R - R') n},$ where $n = \frac{\Delta N > 0}{M}$, which is the average density of particles per M lattice site in the case of no potential energy of interaction (V=0). The MPA yields

 $T_c = 4(E_B^{+5}e_1^{+6})$

at the critical point. The values of the energy parameters are

adjusted in order to reproduce the experimental critical temperature. The result gives

$$E_{\rm B}$$
 = 4.65 kcal/mole $e_{\rm I}$ = $e_{\rm Z}$ 7.2 , 10^{-2} kcal/mole .

Fleming and Gibbs have derived the following critical parameters Using experimental values for the nearest neighbor separation,

There is a sizeable discrepancy with respect to the experimental

made with experimental results. The second and third virial coefficients have also been calculated with good result for the former and unsatisfactory result for the latter. This is not surprising any angular correlation effect in the MPA, no comparison has been in view of the fact that the third virial coefficient reflects Grand Partition function, but in view of the total neglect of An equation of state has also been derived from the three body and higher interactions.

In a more recent paper, Bell and Sallouta have modified the basic structural model in order to obtain an exact solution. molecules are considered to be hydrogen bonded and their interaction energy is -w. In the opposite case, they are unbonded primary lattice sites along the bonds between the molecules. This was done by placing the interstitial sites between the If an interstitial site is unoccupied, the two neighboring and their interaction energy becomes -e.

together with zeroth and first order approximations in the framework Exact computations have been performed with this model

of the Ising model. Two-dimensional lattice structures given by a honeycomb framework and a plane square lattice have been treated and exact solution have been obtained. The three dimensional diamond lattice has also been treated and solved exactly. The exact results have been compared to both the zeroth and first order approximations. It has been found that for appropriate values of the ratio of the energy parameters e and w, density maxima and compressibility minima can be obtained together with a qualitative agreement with the experimental vapour-liquid phase diagram. In all the cases, the first order treatment, which is equivalent to the Guggenheim-WcGlashan scheme mentioned in the preceding section, has been found to give results in good agreement with the outcome of exact calculations.

THE MODEL OF WERES AND RICE

Another approach to the problem of water structure is provided by the cell model of Weres and Rice. In this case the structure of the liquid is believed to be governed by a finite number of basic structural entities which are determined by the different distributions of molecules over a cell composed of 15 lattice points located at the sites of a BCC structure. These distributions are constrained by the geometrical restrictions imposed by the strength and directional characteristics of the hydrogen bonds. Both completely and incompletely bonded molecules are allowed in this model. The probabilities of occurrence of the various basic cell configurations are the determining factors of the structure of the whole system.

An effective pair potential of interaction developed by

-27

Ben-Naim and Stillinger (the BNS potential) is used in the calculations of the various cell partition functions. This pair potential includes two factors: an isotropic interaction represented by the usual Lennard-Jones 6-12 potential, and an angularly dependent electrostatic interaction. This BNS potential is written

$$V(\underline{x}_1,\underline{x}_2) = V_{LJ}(R_{12}) + S(R_{12})V_{elec}(\underline{x}_1,\underline{x}_2)$$
,

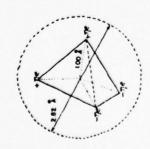

where $\mathbf{v}_{LJ}(\mathbf{R}_{12})$ is the Lennard-Jones potential, $\mathbf{v}_{\mathrm{elec}}$ is the electrostatic potential, and $S(\mathbf{R}_{12})$ is the switching function designed to avoid any divergence as two molecules approach each other. Figure 9 describes the potential and the configuration of the static charges (Bjerrum model) at the origin of the electrostatic interaction. The higher neighbor interactions are neglected, but a correction factor is introduced in the form of a 'communal entropy' based on the vibrational contribution and determined by quantum mechanical methods.

The evaluation of the partition function involves the determination of the contributions from the statistics arising from the association of the molecules to form the macroscopic system, as well as the calculation of the partition function for the individual basic cells.

The number of possible configurations of the basic cells Ω necessary to build the entire system is given by the method of lattice statistics

$$\Omega = \frac{(N/P)_1}{N_1[N(1/-1)]!} \times \frac{(4NP)!}{(NP_h)![N(4\rho - P_h)]!} \times \frac{N!}{(NP_2)!(NP_3)!(NP_4)!} \times$$

$$\left[12(P_h/4)^2\right]^{NP_2} \left[8(P_h/4)^3\right]^{NP_3} \left[2(P_h/4)^4\right]^{NP_4} \left(\frac{1-\rho}{1-P_h/4}\right)^{N(4-2P_h)}$$

$$U(1,2) = V_{J}(R_{2}) - S(R_{12})V_{HB}(1,2)$$

$$V_{LJ} = 4e\left[\left(\frac{\sigma}{R}\right)^{2} - \left(\frac{\sigma}{R}\right)^{3}\right]$$

$$V_{HB}(1,2) = (\eta e)^{2} \sum_{q} \frac{1}{2} \left[\frac{1}{2} + \frac{1}{2} + \frac{q}{2}\right]$$

where: N: the total number of molecules,

NP, the total number of hydrogen bonds,

e . the fraction of occupied states,

 $P_{\underline{1}}:$ the fraction of molecules with i hydrogen bonded neighbors (i=2,3,4).

The evaluation of the basic cell partition function involves various approximations and methods. One is invited to refer to the original paper for the details of the treatment. The main assumptions and arguments are summarized below.

The interactions between a molecule and its neighbors further than the nearest ones are treated in the dielectric continuum approximation: The molecules situated outside a 4 A sphere centered on the molecule of interest are replaced by a dielectric medium.

As a first approximation, the translational and rotational degrees of freedom of the molecules in the cell are treated as independent harmonic oscillators. Their driving potential is approximated by a quadratic function in the deviation from the equilibrium positions (i.e. the lattice positions in the configuration of ideal hydrogen bonding). The magnitude of the vibrational frequencies, however, are such that a quantum mechanical treatment is deemed necessary. Because the dimensions of the cell are allowed to vary linearly with temperature in order to account for thermal expansion, the harmonic oscillators' frequencies are calculated separately at each different temperature.

Some difficulty arises due to the fact that the BNS potential has been derived on exclusively classical considerations. An ad-hoc modification of it is introduced to achieve a better fit

$$\delta E = \left[(e_0 - e_1) + (\frac{1 - K}{1 + K})^2 (e_0 + e_1) \right] (1 - P_v) .$$

The rotational correlation time T2 is defined as

$$T_2 = \begin{cases} < x_2^0 (\theta(t)) x_2^0 (\theta(0)) > dt \end{cases}$$

where r_2^0 (0) = $\frac{1}{2}(\frac{5}{4\pi})^{\frac{1}{2}}(\cos 9-1)$,

fixed direction in the water molecule. T_2 can be calculated under and where 0 is the angle between a fixed direction in space and a the assumption that the water molecule is a spherical top by ------

$$T_2 = \frac{\langle 9^2 >^{\frac{1}{2}}}{4\langle 1-\lambda_2 \rangle} \left(\frac{\pi I}{2kT} \right)^{\frac{1}{2}} \frac{kT}{\delta E} \cdot \exp(\delta E/kT)$$
,

where $I = 1.92 \times 10^{-40}$ g.cm² is the mean moment of inertia, and $\lambda_2 = \exp(\langle \Phi^2 \rangle)$.

The viscosity η can be calculated through $T_2 = \frac{v}{kT} \left(\frac{2^{\frac{k}{2}}}{1-\lambda} E\right)$ exp (-W/kT).

The deuteron spin-lattice relaxation time can be derived

$$\frac{1}{T_1} = \frac{3(\frac{e^2qq}{h/2\pi})^2 T_2}{(\frac{e^2qq}{h/2\pi})^2} , \quad (\frac{e^2qq}{h/2\pi} = 213 \text{ Hz}).$$

The coeficient of self diffusion is derivable from the

$$D = \frac{kT}{4\pi a \eta}$$
, where $a = \sigma/2 = 1.41 A$.

agreement was then obtained with the results of Rahman and Stillinger with the experimental evidence. The oxygen-oxygen pair correlation in good agreement with experimental data. The pressure dependence function was also determined $(g_{00}(R))$ under conditions analogous to those used in Molecular Dynamics computer simulations. A good The computed temperature dependence of $\mathbf{r_1}$, $\boldsymbol{\eta}$, and \mathbf{D} are at atmospheric pressure and under 22 kBars. Only two adjustable of T₁ and D can also be derived from the model, and they agree parameters were used in the fit.

6) THE "BOND LATTICE" MODEL OF ANGELL

liquid water was introduced by C. A. Angell in 1970. The initial A relatively simple, yet successful structural model for "tightly connected random tetrahedral network structure" if it assumption of the model is that the liquid will settle into a

could be cooled down without the onset of crystallization. A random quasi-lattice structure is thus defined for the liquid.

A second lattice is defined with respect to this point lattice and is called the "bond lattice". Each site on this lattice is situated between the sites of the point lattice, i.e. on the lines of the hydrogen bonds connecting the molecules. The ground state of such a bond is postulated as being when the bond is "or.". The breaking of the bond corresponds to an elementary "excitation".

Because of the strains due to the totally connected network, in the event of the breaking of a bond, the molecules reorient themselves cooperatively, seeking a less strained configuration.

The methods of lattice statistics allow the calculation of the equilibrium distribution of broken bonds over such a random network. The regult is given by

$$n_{x} = 2N (1 + exp(e/kT))^{-1} = \frac{2N}{1 + exp(e/kT)}$$

where n_χ is the number of broken bonds, N the number of $\rm H_2^0$ molecules, and e is the energy associated with the breaking of a bond.

This expression has been evaluated under the assumption that the interaction between the lattice elements can be neglected, i.e. a broken bond has no effect on the neighboring bonds. This treatment also assumes that a hydrogen bond can be classified as on or off in a discrete manner.

The configurational heat capacity is given by $c_{\mathbf{v}} = N \kappa \; (e/kT)^2 N_{\mathbf{x}} (1-N_{\mathbf{x}}) \quad \text{where} \; N_{\mathbf{x}} = \frac{n_{\mathbf{x}}}{2N} \; .$

-85

Because there is a change in the vibrational frequency distribution upon breaking a bond, the excitation must be changed to e - ${\tt Ts}_{\chi}$, where ${\tt s}_{\chi}$ is the net increase in lattice entropy upon excitation.

The configurational heat capacity per mole then becomes: $C_{\mathbf{v}} = 2 \, R \, \left(d E/RT \right) . N_{\mathbf{x}} (1-N_{\mathbf{x}}) \, ,$

where N(e-Tsx) = dE+PdV-TdS.

The parameters dE and dS are fixed by calculating the configurational heat capacity of water obtained by using the vibrational contribution in ice. One finds dE = 1.9 kcal/mole of bonds, and TdS = 4.8 cal/mole. They agree with values provided by Eisenberg and Kauzmann to within 5% at all the temperatures considered (250 K to 400 K).

A maximum in the density is also obtained on the basis of the calculated negative values of the expansivity at 0 $^{\circ}$.

By way of the Vogel-Tamman-Fulcher fit of the viscosity data and a postulated probability of molecular rearrangements due to fluctuations in $N_{\mathbf{x}}$, Angell has obtained a very good fit of the temperature dependence of the viscosity. The values calculated for the relaxation time in water also compare well with the experimental values for dielectric relaxation time. The pressure dependence of the viscosity is also in qualitative agreement with experimental evidence.

An improvement of this first order approximation is suggested by Angell and could include the effect of the cooperative behavior of the water molecules. Such a scheme is analogous to the Ising problem with interacting neighboring particles.

-82-

From the results of the lattice and cell models it can be concluded that, although the basic postulation of a solid-like lattice structure seems to be an extremely rough approximation when one is concerned with a fluid, it has been possible to simulate the principal anomalous phenomena exhibited by liquid water. Such an outcome confirms our qualitative view of these phenomena even though it reveals that the methods employed are incomplete, or worse, inadeduate. The main problem remains that of the statistical mechanical treatment of cooperative phenomena as applied to the interactions between the water molecules. A cleverly designed intermolecular potential may eventually provide an approximate treatment, although it is doubtful whether a pair potential, even with quantum effects accounted for, could achieve this task.

The method of Integral equations

1) Generalities

A rigorous statistical treatment of the structure of a macroscopic system would require the exact evaluation of the quantum mechanical partition function

This sum is over all the possible states of the system with the appropriate energy levels $E_{\rm i}$. However, almost invariably the difficulties involved in the computation of $Q_{\rm qm}$ are insurmountable. A first approximation is often taken in the physics of liquids leading to the replacement of $Q_{\rm qm}$ by the classical partition function $Q_{\rm cl}$

$$q_{c1} = \frac{1}{h^{3N} \kappa!} \int ... \int dp^N d\bar{k}^N e^{-\beta H}$$
,

defined for a system of N spherical particles with the hamiltonian represented by H. \underline{P} and \underline{R} are the momentum and position coordinates. One has for the hamiltoman

$$H(\underline{P}^N, \underline{R}^N) = \frac{N}{1 = 1} \frac{P_{\frac{1}{2}}^2}{2m} + U_N(\underline{R}^N)$$
,

where U_N (\overline{R}^N) is the total potential energy of the configuration \overline{P}^N . For a system of non-spherical particles, one must add the angular coordinates to \overline{R}^N ; thus : \underline{X}^N ; (\overline{R}^N , $\overline{\theta}^N$). $\underline{\theta}^N$ could be represented by the set of Euler angles . After integration over the momenta and after assuming that the internal degrees of freedom are independent of a specific configuration, one obtains

$$q_{c1} = \frac{q^N}{(8\pi^2)^N \Lambda^{3N} N!} \int \dots \int d\underline{\chi}^N e^{-\beta U_N} (\underline{\chi}^N)$$
,

allow the derivation of all the thermodynamic parameters. Inforpriate (tractable) potential function for molecular interaction distribution functions can only be accomplished after an approis the 'thermal wavelength' and degree of freedom. density of observing two $H_2^{\,0}$ molecules in the configuration given where ℓ is the bulk density and ℓ $(\frac{2}{X_1},\frac{X_2}{X_2})$ is the probability by the set of coordinates $(\underline{x}_1,\underline{x}_2)$, e $^{(2)}$ is defined by

$$e^{(2)}(\underline{X_1},\underline{X_2}) = \frac{N!\int \dots \int \exp^{-\beta U_N}(\underline{X_1},\dots,\underline{X_N}) \ d\underline{X_3} \dots d\underline{X_N}}{(N-2)!\int \dots \int \exp^{-\beta U_N}(\underline{X_1},\dots,\underline{X_N}) \ d\underline{X_1} \dots d\underline{X_N}}$$

Here $\mathbf{U}_{N}(\underline{X}_{1},\dots,\underline{X}_{N})$ is the effective pair potential of interaction valid for the N particles in the system.

The experimental radial distribution function (RDF) obtained through X-ray or neutron scattering is in effect the angle averaged pair correlation function

$$\bar{g}^{(2)}(\underline{R}_1,\underline{R}_2) = (1/8\pi^2)^2 \int g^{(2)}(\underline{X}_1,\underline{X}_2)^{\mathrm{d}\underline{\theta}_1} \mathrm{d}\underline{\theta}_2,$$

the oxygen atom or the center of mass), and θ_1 denotes the Euler coordinates of a fixed point in the water molecule (generally where $(\underline{\theta_1}, \underline{R_1})$ is equivalent to $(\underline{X_1})$. $\underline{R_1}$ denotes the spatial

sent time there exist only results of computations based on drasvolved in treating the problem of water is such that at the pre-One should state at the outset that the difficulties intic approximations. In consequence, Ben Naim only claims that the results concern "water-like particles". The hope is that

the degree of similarity between these models and water molecules will allow quantitative predictions not too far from reality.

The first step is the derivation of an effective intermolecular potential that will reproduce the main structural features of liquid water. One choice (Ben Naim's) could be the BNS potential described in the preceding section. This potential function has been subsequently modified by Stillinger? Who introduced the ST 2 potential in his works in Molecular Dynamics. Both these potentials are derived on entirely classical assumptions. A partial remedy to this defficiency is provided by the potential function introduced by Popkie et al. Which includes the contribution from electron correlations.

A fairly complete historical survey of the development of effective pair potential of interaction for water can be found in the doctoral dissertation of M. Mruzik.

To evaluate the pair correlation function, Ben Naim has adapted the Percus-Yevick equation. This equation provides a relation between the pair correlation function and the interaction potential. This equation is written

$$y(\underline{x}_1,\underline{x}_2) = 1 + (e/8\pi^2) \int y(\underline{x}_1,\underline{x}_2) f(\underline{x}_1,\underline{x}_2) \Big[y(\underline{x}_2,\underline{x}_2) f(\underline{x}_2,\underline{x}_2) + y(\underline{x}_2,\underline{x}_2) \Big]$$

where f and y are defined as

$$f(\underline{x}_1, \underline{x}_2) = e^{-\beta U_N}(\underline{x}_1, \underline{x}_2)$$
,
d $y(\underline{x}_1, \underline{x}_2) = g^{(2)}(\underline{x}_1, \underline{x}_2)e^{\beta U_N}(\underline{x}_1, \underline{x}_2)$.

This integral equation must be solved for $y(\underline{x}_1,\underline{x}_2)$ when $f(\underline{x}_1,\underline{x}_2)$

has been given an assumed value.

Because of the large amount of computation necessary to solve this equation, an additional approximation is introduced which conveniently averages out all the angular coordinates and reduces the equation to three dimensions.

3) Evaluation of average thermodynamic functions.

Once the pair correlation is known, one can derive the average thermodynamic functions using certain relations.

For the internal energy one has

$$\begin{split} E = & 3/2\mathrm{NkT} + \frac{1}{2} \int d\underline{x}_1 \int d\underline{x}_2 \mathrm{U}(\underline{x}_1,\underline{x}_2) \, \mathrm{e}^{(2)}(\underline{x}_1,\underline{x}_2) \\ = & 3/2\mathrm{NkT} + (\mathrm{N}\,\mathrm{e}/\mathrm{L6}^{-2}) \int d\underline{x}_1 \mathrm{U}(\underline{x}_1^1) \, \mathrm{e}^{(2)}(\underline{x}_1^1) \, , \end{split}$$

where $\underline{X_1}$ are the reduced coordinates taken with respect to one of the two particles.

The pressure is given by the relation

$$P = \text{kTe} - (1/6\text{V}) \ \int \! d\underline{x}_1 \ \int \! d\underline{x}_2 \Big[\overline{R} \cdot (\text{aU/aR}) \Big] \, \mathrm{e}^{-(2)} \left(\underline{x}_1 \cdot \underline{x}_2 \right) \, ,$$
 where $\overline{R} = \underline{R}_2 - \overline{R}_1$.

The two relations given above depend upon the choice of the effective pair potential and must be complemented by contributions arising from higher orders interactions for a more accurate treatment. One relation which is valid for all potential functions (i.e. which does not need pairwise additive assumption) is the compressibility equation

$$\theta_T = (1/kTe) + (1/kT) \int dR \Big[g(\underline{R}) - 1 \Big] = (1/kTe) + (1/kT) \int \Big[g(\underline{R}) - 1 \Big] \, 4 \pi R^2 dR \, .$$
 A great advantage of this relation is that it involves only the

radial distribution function g(R). Once this is known, it becomes possible to calculate 9T.

Some of the results.

The Percus-Yevick equation has not allowed a solution for the regular BNS potential. An additional parameter had to be introduced to control the degree of the electrostatic contribution (or hydrogen bond contribution). The modified BNS potential is written

$$U(\underline{x}_{1},\underline{x}_{2},\lambda) = U_{\rm LJ}(R_{12}) + \lambda S(R_{12})U_{\rm el}(\underline{x}_{1},\underline{x}_{2}) \ ,$$

molecules) is too high (7.4 instead of 4.4 found experimentally). Lennard-Jones particles. As A is gradually increased to a maximum value of 0.3 (beyond which no solution can be obtained), the peaks in the RDF match reasonably well for A=0.3. However, the improves significantly. The positions of the first and second within a sphere of arbitrary radius R centered on one of the λ≈0 is the rough approximation corresponding to the case of agreement between the computed RDF and the experimental one computed coordination number (number of molecules contained

 10^{-16} sec are required due to the strong molecular interactions. momenta of all the particles are calculated after a time step &t. information gathered. For liquid water time steps as short as Thus, the true total duration of a simulation with $10^{4}~{\rm to}~10^{5}$ use of an effective pair potential, and the new positions and calculation time used by the computer and the large amount of This procedure is repeated for the next configuration and the next time step. Obviously, this procedure is limited by the equal to or longer than the time constants for most kinetic time steps is usually around 10-11 to 10-12 sec. This is processes on the molecular scale.

A great deal of work in Molecular Dynamics simulation has been accomplished by Stillinger and Rahman. Some of their results are considered here. A modified version of the BNS potential described in a Molecular Dynamics study of liquid water under normal and elepreceding section, the ST 2 potential, has been used in the vated pressures.

04 molecules contained in a cubical 'box' of edge length of 18.62 have been considered. The temperature is determined from the In a first study (at a density of 1 g/cm³) 216 rigid total kinetic energy of an assumed thermalized system by

than that from X-ray scattering. A broad peak is obtained through of the first peak does not differ by more than 0.01 A . The peak is qualitatively similar to the behavior of the experimental RDF. height from Molecular Dynamics, however, is significantly higher almost the same temperature (10 C instead of 4 C), the position tetrahedral structure is preserved. The remaining disagreement temperatures. The agreement for $\varepsilon_{\rm 20}({\mbox{R}})$ between the calculated between computed and experimental data is tentatively assigned to quantum corrections. The temperature dependence of the RDF pair correlation functions \$60, 80H, and 8HH at four different Stillinger and Rahman have also determined the nuclear the calculations at around 4.5 A indicating that some of the and the experimental results (of Narten et al.) is good.

(with a density of 1.346 g/cm3, equal to the density at the triple Molecular Dynamics simulation of water under high pressure under 22 kbars) has yielded evidence of a denser packing than at atmospheric pressure by a factor of almost two: The mean number of neighbors out to the position of the first minimum is found Stillinger and Rahman reject the possibility of describing the analogous to that of ice VII since the coordination number for point of iceVI, ice VII, and liquid water, i.e. at 81.6 C and to be equal to 10 instead of 5.38 at 97 C and one atmosphere. liquid structure at the higher density by a crystal structure

Stillinger and Rahman do not view the existence of large cavities there does not seem to be a way for interstitial molecules to that type is only 8. Upon melting, the volume increases, and contribute to an increase in coordination number. Moreover, in ice VII as highly probable.

involves an analysis of the consequences of the artificial cut-off that the application of pressure decreases the structural contribution to the specific heat by hindering the molecular rearrangetask of computation. The density of the liquid under saturation at a density of 1.346 g/cm3). This is consistent with the idea experimental value is 18.0 cal/mole.deg). This discrepancy is The evaluation of thermodynamic quantities $(C_{\mathbf{v}},~\epsilon~,\beta_{\mathbf{r}})$ point for pair interaction arbitrarily introduced to ease the $C_{\mathbf{v}}$ was found to be much lower $(C_{\mathbf{v}}=17~\text{cal/mole.deg}$ at 97 C and values obtained for $C_{\mathbf{v}}$ (34.7 cal/mole.deg) is too high (the conditions exhibits a maximum at 27 C where $e = 1.0047~g/cm^3$ (as opposed to 4 C and 1.0 g/cm^3 found experimentally). The also attributed to quantum effects. Under elevated pressure

the velocity auto-correlation function o(t) which is defined as The self-diffusion coefficient can be calculated through

and one can compute D (the self-diffusion coefficient) with
$$D = \lim_{n \to \infty} \frac{\langle \delta B_1(t) \rangle^2}{\sqrt{(t+1)^2}},$$

and

 $\int_{dt}^{d} \langle \delta R_j(t)^2 \rangle = 2 \int_{0}^{t} dt' \langle \underline{v}(0), \underline{v}(t') \rangle .$

during the displacement of the center of mass of the molecule j during the time t. The values calculated for D are about 30 % larger than those determined experimentally. One interesting effect was obtained in the study under higher pressure: An increase in the density by over 30 % only induces a decrease of slightly more than 10 % in the value of D. In close packed fluids like Argon, such a increase in density results in a drastic reduction in the value of D. This has been interpreted as evidence for the phenomenon of increased fluidity in liquid water with an initial increase of pressure.

Wolecular Dynamics experiments do not provide any evidence for the This could be interpreted as a decrease in the number of hydrogen With the energy of the hydrogen bond retained as a variable parameter, they have found that in every case such a distribution was rature under low pressure has been obtained through calculations singly peaked. A multiply peaked distribution would have to be bution of molecules in terms of their number of hydrogen bonds. in the liquid. Stillinger and Rahman have computed the distri-Evidence for hydrogen bond breaking with rising tempepresence of two or several different types of structures mixed probability of molecular pairs having higher potential energy. tonds due to the higher temperature. However, the results of found in the case of a mixture of distinct types of molecular temperature is raised, this distribution shifts to a higher of the pair interaction distribution function P(V). As the environments.

In conclusion, it appears that the computer simulation

-101-

methods are able to reproduce the essential features of liquid water under low pressure. The Monte Carlo method, with the use of a more accurate potential function, has achieved a better agreement with experimental values for equilibrium properties. The possibilities of the method of Molecular Dynamics are greater. Its achievements cannot yet be fully evaluated, however, because of the lack of rigorously valid experimental data. Quantum corrections to the Molecular Dynamics results may improve their quality, and more extensive studies may confirm the high pressure results. An attractive possibility is the study of phase transitions and the processes of nucleation. Finally, because exact computations can be carried out with these methods, the results they provide could be used as standards for judging those obtained through the use of more approximate techniques.

PROPERTIES AND STRUCTURE OF THE WATER AN OVERVIEW

WATER! AN OU

the various models dealing with the structure of water. The semi empirical "ad-hoc" models are described together with the "lattice" and "cells" models, as well as the methods of integral equations and computer simulations. The results of a few representative works are summarized in an attempt to obtain a general picture of the present status of this field. This work is by no means exhaustive, to include all the existing works is a task outside of the scope of this contribution.

KEY WORDS (Continue on reverse side if necessary and identify by block number)

This work is an attempt at presenting an overview of the field of liquid water. The first chapter contains a summary of some of the known thermodynamic, transport, and molecular properties of this liquid. The supercooled and superheated liquid ranges are considered due to the relatively recent interest in those uneasily accessed states. The second chapter contains a cursory review of
